**Itch is one of the most distressing sensations that substantially impair quality of life. It is a cardinal symptom of many skin diseases and is also caused by a variety of systemic disorders. Unfortunately, currently available itch medications are ineffective in many chronic itch conditions, and they often cause undesirable side effects. To develop novel therapeutic strategies, it is essential to identify primary afferent neurons that selectively respond to itch mediators as well as the central nervous system components that process the sensation of itch and initiate behavioral responses. This review summarizes recent progress in the study of itch, focusing on itch-selective receptors, signaling molecules, neuronal pathways from the primary sensory neurons to the brain, and potential decoding mechanisms based on which itch is distinguished from pain. [BMB Reports 2016; 49(9): 474-487]**

## INTRODUCTION

Pruritus, or itch, is a sensation that provokes scratching or the desire to scratch (1). Chronic itch is a major distressing symptom associated with many diseases of dermatological, systemic, neurological, or psychogenic origin (2, 3). For example, extreme itch is a cardinal symptom of atopic dermatitis, which affects an estimated 17% of the world's population, primarily infants and children in urban areas and developed countries (4, 5). Itch is also a common symptom associated with dry skin in the elderly population, experienced by 30-60% of the elderly (6). Pruritus often arises as a side effect of medications and therapies, leading many patients to discontinue treatment. For example, ~30% of African malarial patients refuse to take the anti-malarial drug chloroquine because of unbearable itch (7, 8). Chronic itch sufferers frequently cause self-harm through uncontrollable itch-scratch cycles.

Despite the presence of evident clinical significance, our knowledge about etiology and neurobiology of itch is far from complete. In order to develop new and highly selective treatments for a wide variety of persistent itch conditions, we must understand the underlying peripheral and central mechanisms of acute and persistent itch. This review summarizes current knowledge of the molecular and cellular mechanisms underlying itch in the primary afferents and spinal cord and highlights the anatomical structures in the brain that are involved in the sensation and modulation of itch.

## PRURICEPTIVE PRIMARY AFFERENTS

Pruritogens (itch-causing compounds) are produced endogenously, introduced from the environment, or delivered as medications (9-11). They bind to specific receptors expressed in free nerve endings of primary sensory neurons innervating the skin, cornea, and mucous membranes. Activation of itch-specific receptors leads to induction of receptor potentials, which, in turn, are transformed into action potentials in nerve endings. The electrical signals travel alongside the primary sensory neurons to reach the central terminals innervating the dorsal horn of the spinal cord or the trigeminal subnucleus caudalis (Vc) (Fig. 1).

In the past decade, significant progress has been made in understanding the peripheral mechanisms of itch. Molecular and mouse genetic approaches have identified itch-sensitive receptors and specific molecular markers that label pruriceptive neurons and also revealed potential drug targets for treating itch. In addition, *in vivo* extracellular recordings have identified sensory nerve fibers and spinal cord neurons that can be activated by cutaneous pruritogens. Together with human psychophysical studies, these techniques have underscored the strong correlation between neuronal activity and itch sensation.

Itch can be classified into two categories, histaminergic and nonhistaminergic, according to the degree of responsiveness to histamine (9). Histamine, the best-studied itch substance, is a bioactive amine released by mast cells and epithelial cells (12, 13). Intradermal application of histamine produces intense itch, with a flare around the application site (14, 15). Histamine binds to specific receptors in the plasma membrane, such as the H1 and H4 receptors, leading to the activation of downstream target molecules within sensory neurons, including G protein, phospholipase C, phospholipase A<sub>2</sub>,

**Fig. 1.** Itch signaling pathway. Schematic illustrating the transmission of itch from the primary sensory neurons to the brain. Itch stimuli (pruritogens) activate itch-sensing neurons in the dorsal root ganglion (DRG) that innervate the skin, which then stimulate second-order neurons in the spinal cord and multiple brain regions. Indicated in the tables are pruritogens, itch-selective molecules and receptors expressed in the primary sensory neurons and spinal cord, and brain regions activated by cutaneous application of a pruritogen. STT, spinothalamic tract; SPA, spino-parabrachio-amygdaloid pathway; PFC, prefrontal cortex; SMA, supplementary motor area; PMC, premotor cortex; M1, primary motor cortex; S1, primary somatosensory cortex; S2, secondary somatosensory cortex; CC, cingulate cortex; IC, insular cortex; BG, basal ganglia; GRP, gastrin-releasing peptide; GRPR, gastrin-releasing peptide receptor; BNP, B-type natriuretic peptide; NPRA, natriuretic peptide receptor A; NK-1, neurokinin-1; H1, histamine H1 receptor; PLCβ3, phospholipase C β3; PLA2, phospholipase A2; 5-HT, 5-hydroxytryptamine (serotonin); 5-HT-2, 5-HT receptor subtype 2; PAR2, protease-activated receptor 2; Mrgpr, Mas-related G-protein-coupled receptor; ET-1, endothelin-1; ET<sub>A</sub>, endothelin-1 receptor A; BAM8-22, bovine adrenal medullary peptide 8-22.

12-lipoxygenase, and the capsaicin receptor TRPV1 (16-19). It has been shown that phospholipase β3 (PLCβ3) mediates increase in intracellular calcium level in primary sensory neurons elicited by activation of the histamine H1 receptor (17). Mice deficient in PLCβ3 showed a significant defect in scratching behavior elicited by histaminergic pruritogens, including histamine, a selective H1 agonist histamine-trifluoromethyl toluidine, and the mast cell activator compound 48/80 (17). Histamine-evoked electrophysiological and behavioral responses are substantially reduced by genetic deletion of TRPV1 in mice or by specific inhibitors targeting molecules in the histamine signaling pathway (18, 20-22). Mice lacking TRPV1, however, exhibited normal scratching behavior in response to other pruritogens, such as endothelin-1 (ET-1) or 5-HT; whereas, chemical ablation of the central branch of TRPV1<sup>+</sup> neurons leads to a remarkable deficit in scratching in response to those pruritogens as well as histamine, suggesting that TRPV1<sup>+</sup> neurons are able to detect both histaminergic and nonhistaminergic pruritogens (17, 22).

In recent years, nonhistaminergic itch has been a main focus of itch research because many chronic itch conditions are not readily alleviated by antihistamine. Cowhage (*Mucuna pruriens*) is a tropical legume that evokes intense itch as well as pricking, stinging, and burning sensations in humans and scratching in monkeys and mice (23-30). As cowhage-evoked itch is not diminished by antihistamine, it has been the preferred tool for exploring neuronal mechanisms of nonhistaminergic itch. When cowhage spicules are inserted into the skin, the cysteine protease mucunain is released and diffuses to reach nearby nerve endings of primary sensory neurons in the epidermis, thus activating protease-activated receptor (PAR) 2 and 4 (23, 31, 32). PARs, members of the G protein-coupled receptor superfamily, are activated by synthetic peptides that match the sequence of the tethered ligands at the receptor's N-terminus, including Ser-Leu-Ile-Gly-Arg-Leu-NH<sub>2</sub> (SLIGRL) (33). Cutaneous application of SLIGRL elicits scratching behavior in animals (34). PAR2 and tryptase, the endogenous PAR2 agonist, are markedly increased in the

skin of atopic dermatitis patients (35).

A large family of sensory neuron-specific G protein-coupled receptors known as Mas-related G protein-coupled receptors (Mrgprs) plays a key role in detecting nonhistaminergic pruritogens (36). MrgprA3 is expressed in a tiny subset of sensory neurons (4-5%) classified as peptidergic C-fibers (37). It has been identified as a receptor for a pruritic antimalarial medication, chloroquine, which evokes intense itch in humans, particularly those of African descent (7, 38). *In vivo* extracellular recordings reveal that MrgprA3<sup>+</sup> neurons are not only sensitive to chloroquine but also to histamine, bovine adrenal medulla 8-22 (BAM8-22), cowhage spicules, and even the pungent vanilloid compound capsaicin. BAM8-22, a proteolytic cleavage product of proenkephalin A, provokes itch in humans, usually accompanied by pricking, stinging, and burning sensations (39, 40). Mice ablated of MrgprA3<sup>+</sup> neurons exhibited a substantial deficit in scratching behavior evoked by diverse pruritogens, such as histamine, BAM8-22, SLIGRL,  $\alpha$ -methyl-5HT, ET-1, as well as chloroquine (38). However, in ablated mice, normal response to  $\beta$ -alanine, a supplement for muscle building that causes itch sensations in humans and scratching behavior in mice was noted (41). These findings suggest that MrgprA3<sup>+</sup> sensory neurons are able to detect diverse pruritogens, and a different population of neurons mediates  $\beta$ -alanine-evoked itch.

In fact, MrgprA3 is highly co-expressed with another Mrgpr, MrgprC11, which has been identified as a receptor for pruritic peptides such as BAM8-22, SLIGRL, and the cysteine protease, cathepsin S (38, 42, 43). Mice lacking a cluster of Mrgprs, including MrgprC11, exhibit a substantial deficit in scratching behavior to these pruritogens, but their response to other pruritogens, such as histamine and compound 48/80, remains normal (38, 42-44). Since mice lacking PAR2 exhibit a normal response to subcutaneously injected SLIGRL, MrgprC11 is contemplated to be a major contributor to SLIGRL-evoked itch (42).

MrgprD has been identified as a receptor that is specifically activated by  $\beta$ -alanine (45), and mice lacking MrgprD fail to exhibit scratching after intradermal injection of  $\beta$ -alanine (41). Since MrgprA3 and MrgprD are expressed in distinct subpopulations of C-fibers in mice, MrgprA3<sup>+</sup> neurons are unresponsive to  $\beta$ -alanine in *in vivo* extracellular recordings, and mice ablated of MrgprA3<sup>+</sup> neurons are normal in response to  $\beta$ -alanine, these receptors are apparently expressed in two distinct populations of pruriceptive neurons (46, 47).

It has been reported that TRPA1 is one of the key players in Mrgpr-mediated itch (48). For example, chloroquine and BAM8-22 activate a subset of TRPA1-expressing sensory neurons. Cultured sensory neurons isolated from TRPA1-deficient mice exhibit a remarkable reduction in calcium responses evoked by chloroquine and BAM8-22, but their histamine-evoked responses are unaffected. Conversely, sensory neurons from TRPV1-deficient mice respond normally to chloroquine and BAM8-22, but their histamine-evoked

responses are substantially reduced. Thus, TRPV1 and TRPA1 are recruited to serve different types of itch, even though TRPA1<sup>+</sup> cells are known to express TRPV1 (49). Mice lacking TRPA1 exhibit almost no scratching behavior upon subcutaneous injection of chloroquine and BAM8-22, but they show normal scratching in response to  $\alpha$ -methyl-5HT, indicating that their deficit is specific to certain pruritogens.

ET-1, a potent vasoconstriction peptide, is produced by mast cells, endothelial cells, and keratinocytes (50, 51). ET-1 elicits the sensation of itch accompanied by flare reactions in humans and scratching in mice (52-54). A monoamine neurotransmitter, 5-HT, also causes itch by activating the 5-HT-2 receptor after cutaneous application (55-58).

It is likely that itch is mediated by several different subpopulations of primary sensory neurons. Some itch-causing substances activate mostly overlapping populations of neurons, since their specific receptors are expressed in the same neurons (e.g., chloroquine vs. BAM8-22; MrgprA3 vs. MrgprC11), and other pruritogens activate distinct populations (e.g., chloroquine vs.  $\beta$ -alanine; MrgprA3 vs. MrgprD). The number of itch-responding sensory neurons and extent of overlap between responding populations are variable, depending on the type of pruritogen, method of delivery, and species.

A substantial body of evidence indicates that the vast majority of pruritogen-sensitive sensory neurons respond not only to pruritogens but also to noxious mechanical, thermal, and/or chemical stimuli (27, 57, 59-61). In human micro-neurography, for example, intradermal injection of histamine preferentially activates a subset of mechanically insensitive C-fibers (C-MIA) over a time-course matching the psychophysical sensation of itch, whereas topical application of cowhage spicules activates a subset of mechano-heat-sensitive C-fibers (CMH) (26, 27, 62-64). Most itch-sensitive C-MIAs and CMHs are also activated by intradermal injection of capsaicin. Thus, histamine and cowhage activate two distinct subpopulations of primary sensory neurons, which also respond to noxious stimuli in humans. In nonhuman primates, however, both histamine and cowhage activate a subset of CMHs that also respond to noxious stimuli, indicating activation of overlapping population of neurons (also respond to noxious stimuli) by pruritogens (27). In line with this finding, native cowhage spicules and heat-inactivated spicules containing histamine applied to the mouse skin activate a subset of CMH; over 60% of histamine-sensitive CMH also respond to cowhage (30). Conversely, half of the cowhage-responsive fibers are also activated by histamine. For the reason that these histamine- and cowhage-sensitive neurons also respond to noxious stimuli, they represent partially overlapping subpopulations of nociceptors. Other studies have also shown that diverse pruritogens activate partially overlapping subpopulations of nociceptors in rodent trigeminal and dorsal root ganglia (38, 54, 65-67).

## PRURICEPTIVE NEURONS IN THE SPINAL CORD AND SPINAL TRIGEMINAL NUCLEUS

Itch-sensitive primary sensory neurons release specific neurotransmitters onto postsynaptic neurons in the spinal cord and Vc, where the itch signal is further processed by local excitatory and inhibitory neurons as well as descending synaptic inputs from the brain, before the itch information is transmitted to supraspinal regions, such as the thalamus and parabrachial nucleus (PB), via ascending neuronal pathways (Fig. 1). Projection neurons comprise only a small fraction of the neurons in the dorsal horn (~5% of lamina I neurons in the L4 segment of the rat spinal cord), and many of them send collateral projections to synapse with multiple brain regions (68).

In conjunction with glutamate and substance P, gastrin-releasing peptide (GRP) has been considered as a key neuropeptide transmitter that is released from either the central terminals of itch-sensitive primary sensory neurons or local excitatory neurons, activating dorsal horn neurons that express the GRP receptor (GRPR) (11, 69-72). GRP is a homolog of bombesin, a 14-amino acid peptide originally isolated from frog skin; intrathecal or intradermal injection of bombesin provokes scratching in animals (71, 73-76). Mice lacking GRPR or ablated of GRPR<sup>+</sup> neurons display a substantial reduction in scratching behavior in response to a variety of pruritogens, such as compound 48/80, SLIGRL, and chloroquine, but normal responses to painful stimuli, indicating that GRPR<sup>+</sup> neurons are selectively involved in itch signaling (69, 76). Consistent with this finding, mice deficient in the testicular orphan nuclear receptor exhibit a near-complete absence of scratching behavior in response to histamine,  $\alpha$ -Me-5-HT, and chloroquine (77). In these mice, ~80% of GRP<sup>+</sup> or GRPR<sup>+</sup> neurons are ablated, suggesting the importance of GRP signaling in itch responses (77).

B-type natriuretic peptide (BNP, also known as natriuretic polypeptide B) is another itch-specific neurotransmitter expressed in a subset of primary sensory neurons that co-express MrgprA3, TRPV1, and PLC $\beta$ 3 (71). It is released from the central terminals of these neurons to activate the postsynaptic second-order neurons in the spinal cord. Mice lacking in BNP exhibit greatly attenuated responses to a range of pruritic agents but retain normal reactions to thermal, touch, and proprioceptive stimuli. Conversely, intrathecal injection of BNP induces robust scratching in mice. Consistent with these findings, ablation of spinal interneurons expressing NPRA, a receptor for BNP, leads to a major attenuation in itch responses to intradermal injection of histamine or intrathecal administration of BNP, but normal reactions to other somatosensory stimuli. Thus, BNP signaling plays a key role in itch transmission. It has been proposed that NPRA<sup>+</sup> neurons are the elements upstream of GRPR<sup>+</sup> neurons in itch-transmitting circuits (71).

In order to determine the neural basis of itch processing in

the spinal cord, *in vivo* single-unit recordings have been performed from the spinal cord and Vc, following application of itch stimuli to the skin. The dorsal horn neurons can be classified according to their responsiveness to mechano-insensitive and noxious mechanical stimuli, into: 1) mechano-insensitive (MI), 2) low-threshold, 3) wide dynamic range (WDR), and 4) nociceptive-specific (NS) neurons (11, 78-80). WDR neurons respond to both innocuous and noxious mechanical stimuli, with higher-frequency discharges in response to noxious stimuli.

*In vivo* recordings have shown that the vast majority of itch-sensitive neurons in the spinal cord and Vc are WDR and NS neurons, and only a few are MI neurons. Most of these neurons are nociceptors that also respond to noxious stimuli. For example, in nonhuman primates, histamine and cowhage activate two mostly separate subpopulations of neurons in the spinal cord, all of which are either WDR or NS neurons that also respond to noxious mechanical or thermal stimuli, indicating that histaminergic and nonhistaminergic itch are carried by two separate subpopulations responding to nociceptive stimuli (60, 61, 81). Antidromic mapping has revealed that the neurons involved are the spinothalamic tract (STT) neurons projecting into the ventrobasal and posterior nucleus of the thalamus. Similarly, in rodents, the dorsal horn of the spinal cord and Vc contain a number of pruritogen-sensitive neurons, mostly WDR and NS neurons that also respond to noxious stimuli (11, 54, 57, 65, 82, 83). These findings also support the concept that itch information is mediated in the spinal cord and Vc by a subset of nociceptive neurons responding to noxious stimuli. Only a small fraction of itch-sensitive neurons are MI. Previous research in cats has identified a small number of histamine-sensitive MI neurons from the STT (84). Half of all histamine-sensitive neurons are unresponsive to the noxious chemical mustard oil, indicating the existence of itch-specific neurons that are insensitive to noxious mechanical or chemical stimuli. However, the response of CMHs was not examined in the reported study.

It is likely that the vast majority of pruritogen-responsive neurons are local interneurons, since only a small subset of pruriceptive neurons in the spinal cord and Vc are projection neurons that innervate either the thalamus or PB in mice (85).

## NEURAL CODING MECHANISMS OF ITCH AND PAIN

Itch is closely linked to pain, and electrophysiological studies have shown that the majority of itch-sensitive neurons are nociceptors, thus raising an important question as how itch is differentiated from pain. Both itch and pain are complex sensory and emotional experiences created by neuronal activities in the peripheral and central nervous systems. They are detected by a subset of primary afferents in the somatosensory system, mainly by slowly conducting unmyelinated C-fibers and thinly myelinated A $\delta$ -fibers (9, 29, 86). The similar sets of receptors and signaling molecules are

involved in transducing itch and pain within sensory neurons. As such, pruriceptive and noxious stimuli often activate the shared populations of neurons. Moreover, alleviation of pain can produce a sensation of itch; morphine, for example, inhibits pain but causes a sensation of itch in humans and scratching behavior in animals (87-89). Conversely, itch is temporarily relieved by scratching. Finally, it is apparent that both itch and pain elicit unpleasant sensations. However, they clearly evoke qualitatively different sensations and behavioral responses, suggesting that there should be a mechanism based on which itch and pain can be differentiated.

There have been debates on the neural basis of itch processing. For many years, itch has been considered as a sub-modality of pain in which itch and pain are served by the same population of neurons, and the sensation is determined by the pattern of neuronal activity; itch is elicited when sensory neurons are activated weakly, whereas pain is evoked when neurons are strongly activated (9). This so-called intensity theory was supported by the experimental finding that most of the itch-sensitive neurons also respond to painful stimuli. Moreover, high doses of pruritogen produce pain, whereas low doses of algogen evoke itch. For instance, intradermal injection of a high concentration of histamine elicits pain (90, 91). Conversely, capsaicin, which normally causes intense burning pain when injected intradermally, elicits itch when delivered topically or applied as heat-inactivated cowhage spicules coated with capsaicin (28, 91-95).

Primary afferents and postsynaptic neurons in the spinal cord exhibit relatively higher-frequency discharges in response to noxious stimuli than do pruritogens (30, 54, 60, 61, 65, 81-83, 96). For example, capsaicin provokes higher-frequency discharges in the trigeminothalamic and STT neurons as compared to histamine or cowhage (30, 60, 81, 96). The manner in which information contained in the pattern of activity is used to produce specific sensation of itch in higher-order neurons in the brain remains to be determined. There exists experimental evidence that challenges the intensity theory. For instance, an itch sensation provoked by neuronal or cutaneous electrical stimulation does not transform into pain at higher-frequency stimulation (97, 98). Also, a specific firing pattern of CMHs does not correlate with itch and pain sensation in humans (99). Since these studies have focused on primary afferents, it remains unclear whether intensity coding is a valid mechanism in the spinal cord and brain.

A number of pieces of genetic and behavioral evidence support another theory, the "labeled line" theory, in which specific populations of neurons are dedicated to serving either itch or pain. For example, mice ablated of either *MrgprA3*<sup>+</sup> primary sensory neurons, *GRPR*<sup>+</sup> neurons in the spinal cord, or *NPR1*<sup>+</sup> neurons in the spinal cord, or mice lacking *BNP* all exhibit a selective deficit in scratching behavior in response to a variety of pruritogens, whereas these manipulations have no

effect on nociception (37, 69, 71). In an elegant genetic experiment, TRPV1-knockout mice were engineered to express TRPV1 only in itch-sensitive *MrgprA3*<sup>+</sup> primary sensory neurons (37). When capsaicin was applied, these animals exhibited only itch-related behaviors without pain-related behaviors; even though *MrgprA3*<sup>+</sup> neurons were found to respond to noxious stimuli in electrophysiological recordings. To accommodate the discrepancies in the electrophysiological and behavioral findings, a new theory, known as "population coding" was proposed, in which the sensation of itch is elicited by activating "pruriceptive nociceptors" that respond to both pruriceptive and noxious stimuli in electrophysiological recordings; in contrast, the sensation of pain is elicited by noxious stimuli, which activate an additional population responding only to noxious stimuli (9, 11). The activity in the "nociceptive-specific" population is speculated to prevent or mask itch transmission by the pruriceptive nociceptors, possibly via local inhibitory mechanisms.

Several lines of evidence support this model. First, selective deletion of vesicular glutamate transporter 2 in a subset of nociceptive neurons leads to spontaneous scratching and capsaicin-evoked itch in mice, suggesting that baseline glutamatergic signaling inhibits itch transmission (100, 101). Second, activity-dependent silencing of a subset of nociceptors using the lidocaine derivative QX-314, followed by activation of another subpopulation of nociceptors, elicits scratching rather than pain behavior in mice (102). QX-314 permeates through activated ion channels such as TRPV1 and inhibits neuronal firing by blocking voltage-gated channels inside the cell. Finally, selective ablation of inhibitory interneurons expressing the transcription factor basic helix-loop-helix domain-containing, class B5 (BHLHB5) results in a substantial elevation of spontaneous scratching, suggesting a potential role for these neurons in suppressing itch transmission by pruriceptive nociceptors (103). A recent study has shown that transplantation of precursors of cortical inhibitory neurons in the spinal cord can rescue the itch-related phenotypes of these mice, presumably by restoring inhibitory mechanisms in the spinal cord (104). The local circuit involving BHLHB5 neurons remains to be determined.

## ITCH PROCESSING IN THE BRAIN

One of the major insights that has emerged from pain studies is that chronic pain is a disease not only of the primary sensory neurons and spinal cord but also of the brain. Chronic pain causes functional and structural alterations in the brain and also affects other functions of brain such as emotion, motivation, and memory. Therefore, developing an effective itch treatment must take into consideration a therapeutic strategy targeting the brain.

Itch is a multidimensional experience that involves perception of the sensory and emotional-affective aspects of itch as well as an urge to scratch employing the motor system (1).

Brain imaging studies have shown that cutaneous application of pruritogens (cowhage and histamine) or electrical stimulation lead to activity changes in multiple brain regions of healthy subjects and chronic itch patients (R, right hemisphere; L, left hemisphere; bi, both hemispheres). Unless otherwise indicated with (↓), all regions were activated during pruritic stimulation. \*Mixed activity (both activation and deactivation) was found within a region. The perception of itch occurs in the brain by interpreting the neuronal activities stemming from projection neurons in the spinal cord and Vc that receive itch signals from pruriceptive primary afferents.

Our current knowledge on itch processing in the brain is derived from a small number of brain imaging studies performed on human subjects, which have utilized techniques such as positron emission tomography, functional magnetic resonance imaging, and magnetoencephalography. Itch was produced in healthy subjects by histamine, cowhage, or electrical stimulus delivered locally to the skin, leading to increased or decreased cerebral activity as well as the sensation of itch (Table 1). A few studies focused on itch processing in the brain of chronic itch patients suffering from atopic dermatitis or end-stage renal disease (ESRD), and other studies tested cerebral activity during suppression of itch (Table 2).

As mentioned above, itch-mediating projection neurons in the spinal cord and Vc are a small subset of WDR and NS neurons that also respond to noxious stimuli. Thus, it is highly likely that itch and pain share common neuronal pathways to and within the brain. Consistent with this idea, brain regions activated by pruritic and noxious stimuli overlap extensively (105-107). Pruriceptive STT neurons send their axons across the midline of the spinal cord and ascend within the anterolateral column pathway to reach the contralateral thalamus, particularly within the ventroposterior medial or posterior thalamic nuclei (60, 61, 81, 84, 108). As is true for pain, itch information may be further relayed to the primary (S1) and secondary (S2) somatosensory cortices, insular cortex (IC), and cingulate cortex (108, 109). Multiple studies have demonstrated thalamus as one of the prominent regions, which is consistently activated by histamine and cowhage (106, 110-113). Interestingly, cowhage elicits more extensive

Activity changes in brain regions during suppression of itch transmission by cold block, scratching (active scratching by subjects or passive scratching by experimenters), butorphanol (a mixed action opioid), or acupuncture (R, right hemisphere; L, left hemisphere; bi, both hemispheres). Unless otherwise indicated with (↓), all regions were activated during itch suppression. Brain imaging was performed following a VAC application to the itchy skin when the sensation of itch was either increasing\* or at peak\*\*. dIPFC, dorsolateral prefrontal cortex; dmPFC, dorsal part of medial prefrontal cortex; vmPFC, ventral part of medial prefrontal cortex; IPFC, lateral prefrontal cortex; vIPFC, ventral lateral prefrontal cortex; OFC, orbito-frontal cortex; MFG, middle frontal gyrus; MFC, medial frontal cortex; LFC, lateral frontal cortex; SMA, supplementary motor area; PMC, premotor cortex; M1, primary motor cortex; S1, primary somatosensory cortex; S2, secondary somatosensory cortex; ACC, anterior cingulate cortex; preACC, pregenual anterior cingulate cortex; subACC, subgenual anterior cingulate cortex; MCC, midcingulate cortex; PCC, posterior cingulate cortex; dPCC, dorsal posterior cingulate cortex; vPCC, ventral posterior cingulate cortex; IC, insular cortex; aIC, anterior insular cortex; pIC, posterior insular cortex; NAc, nucleus accumbens; PC, parietal cortex; BG, basal ganglia; TH, thalamus; VTA, ventral tegmental area; PAG, periaqueductal gray; AD, atopic dermatitis; ESRD, end-stage renal disease; NLS, nonlesional skin; VAC, verum acupuncture.

activation in the thalamus as compared to histamine, as well as in other regions such as the IC, claustrum, globus pallidum, and putamen, consistent with the finding that cowhage-responsive STT neurons in nonhuman primates innervate larger areas within the thalamus than do histamine-responsive STT neurons (81, 113). Overall, both the pruritogens activate mostly overlapping regions. The S1 and S2 are specialized for receiving sensory input and are thought to participate in processing the sensory-discriminative aspect of itch. Since activity in the S1 is positively correlated with the intensity of an itch stimulus, this region is speculated to play an important role in interpreting the intensity of stimuli (105). Several studies report activation of the S2, but its role in itch is unclear (106, 111, 113, 114).

The IC is known to mediate the integration of autonomic, visceral, and limbic functions (115). It is connected to many other regions in the brain, including the cingulate gyrus, frontal, parietal, and temporal lobes, as well as subcortical structures such as the thalamus, amygdala, and brainstem (116, 117). Previous studies have shown that the IC can be roughly divided into several subregions with unique connectivity and functional features (118). The anterior agranular insular cortex (aIC) is connected mainly to other cortical areas and plays a role in creating awareness of bodily states by integrating autonomic and interoceptive information, whereas the posterior granular part (pIC) receives nociceptive inputs from the primary afferents via the brainstem and thalamic nuclei to mediate pain processing (115, 119, 120). It has been shown that itch activates both the aIC and pIC (107, 112). The activity in the aIC is positively correlated with the unpleasant sensation of itch, while the activity of the pIC is correlated with the intensity of the itch stimulus (105-107, 111-113). In ESRD patients with chronic itch, bilateral activation of the IC is observed even in the absence of pruritogen stimulation (114).

The cingulate cortex is one of critical brain regions contributing to the processing of the affective component of pain (121). For example, the anterior cingulate cortex (ACC) is activated upon anticipation or response to acute noxious stimulus or during chronic pain (122). Consistently, surgical damage to the cingulate cortex in humans decreases the affective response to noxious stimuli, while leaving intact the ability to localize the unpleasant stimuli (121, 123). The ACC is also activated by itch stimuli, mainly in its dorsal part (dACC) as well as in the anterior part of the midcingulate cortex (aMCC) (105-107, 110-114, 124). Since electrical stimulation of the MCC evokes the motivation to act, the dACC/aMCC appears to be associated with recognizing itch stimuli and preparing motor behavior (105, 107, 110-112, 125, 126). Many studies have reported activation of other motor-related regions, including the supplementary motor area, premotor cortex, primary motor cortex, and cerebellum (105-107, 110-114, 124, 126, 127). These regions may play a role in recognizing the location of itch stimuli as well as

organizing and executing motor responses such as scratching (105-107, 110-114, 124, 126, 127). Like the S1, activity in these regions is correlated with the intensity of the itch stimulus (105, 110). Interestingly, scratching the itchy skin also elicits activation of S1, S2, cingulate cortex, supplementary motor area, premotor cortex, primary motor cortex, and cerebellum. The activity is higher when scratching provokes pleasure than when it does not (128-130).

In rodents, the majority (~80%) of projection neurons in the superficial dorsal horn of the spinal cord innervate the PB, which is connected to the amygdala and hypothalamus and also to the IC (131). As described above, *in vivo* single-unit recordings in mice have identified pruriceptive neurons in the spinal cord and Vc that project to PB, implicating the spino-parabrachio-amygdaloid pathway in itch processing (132-134). Brain imaging studies, however, have failed to detect activity changes in the PB, probably because most of the projection neurons in the spinal cord in humans send their axons to the thalamus rather than the PB.

The amygdala is also one of the key cerebral structures participating in the sensation, expression, and modulation of pain (133, 134). In particular, the central nucleus of the amygdala (CeA) is considered the output nucleus of the amygdala and integrates nociceptive information from the cerebral cortex and thalamus as well as nociceptive inputs from the PB (135). A recent study has shown that inhibition of GABA<sub>A</sub> receptors by bilateral microinjection of bicuculline into the rat CeA dramatically increases scratching behavior in acute and chronic itch models, suggesting a role for inhibitory mechanisms in the CeA in itch modulation (136). Although the amygdala appears to be involved in itch processing, its role is still unclear, based on its activation in response to a combinatorial application of histamine and cowhage in one study but inactivated by individual treatment in another study (106, 113, 137).

It has been reported that reversible cold-block or complete transection of the upper cervical spinal cord causes a 30-50% reduction in the inhibition of ongoing spontaneous firing of the dorsal horn neurons caused by scratching in a mouse model of chronic dry itchy skin, indicating that supraspinal mechanisms are partially involved in itch inhibition by scratching (138). Indeed, mosquito allergy-elicited biting behavior is inhibited by an intrathecal  $\alpha(2)$ -adrenoceptor antagonist but increased by the catecholaminergic neurotoxin 6-hydroxydopamine and the  $\alpha$ -adrenoceptor antagonist, indicating that the descending noradrenergic system tonically inhibits itch signaling in the spinal cord (139). Conversely, serotonergic neurons in the rostral ventromedial medulla appear to control itch transmission in the dorsal horn of spinal cord by facilitating GRP-mediated signaling (140). On the other hand, electrical stimulation of PAG inhibits the spiking responses of STT neurons activated by subcutaneous histamine (59). A human PET study has demonstrated that application of a painfully cold stimulus to histamine-evoked itch increases

activity in the PAG, suggesting the possibility of a descending inhibitory mechanism of itch in the PAG (110). PAG was activated in response to scratching induced by cowhage-evoked itch in one study but inactivated in another study (129, 141). Thus, the role of PAG in itch suppression is still disconcerted, and further investigation is necessitated.

## CONCLUDING REMARKS

Compared to the extensive research on pain, itch has received relatively less attention until recently. However, our knowledge about the molecular and neuronal circuit mechanisms of itch detection in the skin and itch transmission within the spinal cord and Vc has greatly expanded during the past decade. Identification of itch-specific receptors and neurotransmitters has provided important insights for development of novel therapeutic strategies that selectively target itch-mediating neurons.

Unfortunately, our current knowledge on the supraspinal processing of itch is limited and relies mainly on a small number of brain imaging studies. The reported studies have revealed that cutaneous pruritogen application activates brain regions involved in somatosensory, limbic, and motor-related functions, such as S1, the thalamus, ACC, IC, supplementary motor area, primary motor cortex, and cerebellum. Since the same brain regions are also activated by noxious stimuli, it is puzzling to note as how itch is distinguished from pain in the brain. Given their distinct sensations and different behavioral responses (scratching vs. withdrawal), there should be a mechanism by which these two sensory modalities are differentiated. One possibility is that a single population mediates both itch and pain, using distinct patterns of neuronal activation, spike timing, or other mechanisms. Another possibility is that the brain regions contain two intermingled or closely adjacent subpopulations that are each specialized for either itch or pain, but cannot be detected in brain imaging studies because of limited spatial resolution. Thus, it is essential to study itch in the brain using molecular genetic approaches to identify itch-mediating brain regions at the level of neuronal circuits and to decipher the neuronal circuit mechanism underlying the interrelationship between itch and pain. A combinatorial approach of the advanced techniques to reveal neuronal circuits, including *in vivo* imaging such as multi-photon microscopy and microendoscopy, functional manipulation tools such as optogenetics and chemogenetics, and population-specific neuronal tracing methods based on pseudorabies and herpes virus, will help us to achieve these goals (142-147).
