#### Abstract

This thesis presents a data-based approach for a train scheduling that aims to minimize passenger waiting time by controlling train departure time and the number of skipped trains. In contrast to existing approaches that rely on a statistical model of passenger arrival, we develop a model based on real-world automated fare collection (AFC) data from a metro line in Daegu, a Korean city. The model consists of decomposing the travel time for each passenger into waiting, riding, and walking times, clustering of passengers by trains they ride and calculating the number of passengers in each train for any given time. Based on this, for a given train schedule, the passenger waiting time of each passenger for the entire AFC data period can be calculated. The problem is formulated using the model under realistic constraints such as headway, the number of available trains, and train capacity. To find the optimal solution, we employed a genetic algorithm (GA). The results demonstrate that the average waiting time is reduced up to $56 \%$ in the highly congested situation. Moreover, letting the trains directly go to the congested station by skipping previous stations further reduces the maximum waiting time by up to $19 \%$. The effect of the optimization varies depending on the passenger arrival pattern of highly congested stations. This approach will improve the quality of the subway services by reducing passenger waiting time.

Keywords: Train timetable, Passenger waiting time, Oversaturated condition, Genetic algorithm.

## I. INTRODUCTION

Due to the advantages of the urban rail systems, including environmentally friendly transportation as well as the capability it provides to travel at a faster and more consistent speed than road-based public transport, there has been an expansion and expected growth of the urban rail transit system. Despite these positive benefits, subway transit is a complex system that integrates both mobility and commercial services where operating costs and service quality is of great importance.

Figure 1. A highly congested subway train.

The service quality of the subway system has a lot to be improved. For example, as shown in Figure 1, highly congested urban rail transit causes a deeply negative experience for passengers about the urban rail system. Occasionally, some passengers are not even able to board because there is no space on the train. The problem is that this is also a disadvantage for the
operator. As more passengers accumulate on the platform, more energy is consumed to maintain a more pleasant environment. Given the fact that the heating, ventilation, and air-conditioning (HVAC) system may represent more than 30 percent of the total expenditure which is generally responsible for the highest energy consumption in subway systems [1], it will inevitably increase the energy consumption for train operations which can generate substantial cost. Reducing a few percentages on energy consumption of HVAC systems would save an impressive quantity of electricity.

Therefore, our objective is to reduce the passenger waiting time and the oversaturation time by adjusting the set of train departure times to improve service quality. However, it is difficult to estimate the oversaturation time of the station since the passenger volume inside the coming train is uncertain. Oversaturation time is the time length that at least one passenger at the station is unable to ride an incoming train due to congestion. It is essential to consider the train oversaturation in the train scheduling problem because it directly affects the passenger travel time. As a result, we face a key challenge to estimate the oversaturation time for efficient and practical subway train scheduling. Moreover, counting people without violating the privacy of individuals is also a challenge that must be considered.

To address these challenges, we propose a new approach to handling the train oversaturation problem by optimizing the passenger waiting time by controlling the train departure time from the start terminal station and, if necessary, letting the trains directly go to the congested station skipping previous stations (train skip plan). To estimate the waiting time and oversaturation time, passenger volume information is required to determine if a train is overcrowded. We estimate the passenger volume on the platform and on the train by utilizing the density-based spatial clustering of applications with noise (DBSCAN) [2]. DBSCAN is used for classifying passengers in the same carriage and travel time decomposition [3] for tracking
passengers' location by time with automated fare collection (AFC) data. The AFC system is a smart card-based payment and fare collection method which automates the ticketing system for a public transportation network, and it has been widely adopted in many metropolitan cities around the world. Utilizing AFC data is with far less privacy concerns and a cost-effective method compare to existing sensor-based estimation [4][5][6]. In addition, existing researches about the train scheduling considering passenger demand typically use passenger arrival rate of each station rather than use more fine-grained data when calculating the passenger waiting time[7][8].

Specifically, the contributions of this work are as the following:

- To our best knowledge, this is the first work to optimize the subway train scheduling by controlling train departure time and applying the train skip plan by utilizing large scale real traffic data from the AFC system.
- In order to improve the service quality of the urban subway system, train scheduling optimization problem is formulated to minimize the passenger waiting time and oversaturation time
- Our experiment results show that the train skip plan and adjusting the train departure time yield better results in highly congested situations. Especially, to reduce the maximum passenger waiting time, it is desirable for the train to skip certain stations and go straight to the congested station.
- Our experiment results indicate that the degree to which the passenger wait time is reduced depends on the passenger arrival pattern and the objective function applied.

## II. RELATED WORK

We provide a summary of previous research close to our work, within the area of passenger volume estimation and train scheduling optimization.

### 2.1. Passenger Volume Estimation

There have been existing studies that estimate the passenger volume in the subway by using sensor-based approaches such as image sensing [4], $\mathrm{CO}_{2}$ sensing [5], and Radio Frequency (RF) -based [6] techniques.

To accurately estimate the crowd size, the most standard solutions are using images from the camera [4], However, not only digital cameras are expensive in cost and require high computational overhead, but also, each camera can cover a limited field of view which restraints the system to monitor beyond designated areas. Additionally, the reliability of these techniques can easily be affected by noise in practical settings where lighting levels can vary, and occlusions may be present. Utilizing $\mathrm{CO}_{2}$ levels [5] is another common approach to estimate the passenger population in subways. Despite the advantages this method has in predicting demand for ventilation with far less privacy concerns than that of utilizing RGB information, the estimation accuracy is low and, hence, the approach does not significantly support in predicting cooling or warming demands. There are also techniques for estimating the number of people using RF sensing [6]. Although various wireless devices can easily obtain signal strength many factors must be taken into account such as diffraction, multi-path, reflection issues. Overall, since the sensors that are used in all of these approaches may not already exist in the subway, separate deployments may be required which require additional cost and maintenance for reliable operation over time.

Those existing methods that estimate the passenger volume not only are privacy-invasive
but since the sensors that are used may not already exist in the subway, separate deployments would be required. Additionally, these devices require high computation and are expensive in cost. In this study, we estimate the passenger waiting time and the number of passengers in the subway system using transaction records of AFC data for minimizing privacy concerns that people might have.

### 2.2. Train Scheduling Optimization

Mathematical optimization is the most popular method of solving the train scheduling problem. Many researchers have proposed lots of subway scheduling optimization models with various objectives such as passenger waiting time minimization [8], energy consumption[8][9] and delay time [10].

In this research, we propose a train timetable scheduling model by considering service quality and operation safety. We compare our approach with three related studies.

Shi et al. proposed a method for optimizing the train timetable considering the oversaturated metro line to minimize total passenger waiting time [11]. Their model does not consider passenger walking time and they assumed that the train running time is pre-given in minute units.

Niu and Zhou presented an integer programming model to adjust train timetables for a heavily congested subway system [12]. Their model requires running time among stations. However, both of these studies do not mention the passenger walking time.

Wang et al. proposed a train scheduling model with the objective of minimizing the total travel time of passengers and the energy consumption of trains [7]. They take into account passenger walking time and even passenger transfer time from other lines. However, they did not evaluate their model with real data. They need the physical distance between two adjacent stations to calculate the train running time and train capacity.

Our approach optimizes the train timetable to minimize the passenger waiting time by placing the number of skipped trains as decision variables as well as the train departure time in heavily congested situations. In contrast to existing approaches [7][8] that rely on a statistical model of passenger arrival, we develop a model based on real-world AFC data in a metro line of Daegu, a Korean city. The train running time between two adjacent stations and the passenger walking time are estimated from the passenger data of the AFC system, and the estimated values are much finer-grained than the existing pre-given data in other studies. Therefore, we can expect more accurate results even if less data is provided in advance.

Moreover, we compare how the optimization effect depends on the passenger arrival pattern. Especially under oversaturation, we classify passenger arrival patterns into single peaks, double peaks, and box-shaped peaks and compare how the decrease in passenger waiting time depends on the objective function such as average waiting time and maximum waiting time for each pattern. Accordingly, the operator may predict how the optimization effect will vary depending on the passenger arrival pattern before applying the optimization.

## III. PROPOSED APPROACH

### 3.1. Overview

Figure 2. System overview.

The proposed model aims to optimize the train departure time from the first station to minimize passenger waiting time. As shown in Figure 2, our system consists of two major parts: train scheduling optimization and passenger volume estimation. First, we estimate the train capacity. Next, we estimate the passenger volume and optimize the train timetable. While performing optimization, we continuously check whether the passenger volume exceeds the train capacity.

To estimate the train capacity, we have to calculate the passenger waiting time and the passenger walking time for each station and the train running time between two adjacent stations. Those times can be estimated by utilizing the travel information, which is including origin, destination, tap-in/out time of each passenger from the AFC data. To calculate the passenger waiting time, by utilizing the DBSCAN, passengers are clustered to group passengers traveling to the same origin-destination and taking the same train. Passengers with the minimum travel time among passengers in the same group are assumed to have a waiting time of zero. Waiting times for other passengers are obtained by subtracting their travel time from the smallest travel time of who is on the same train and in the same OD group. The passenger walking time for each station is obtained by comparing the smallest travel time between each OD group. Train riding times between two adjacent stations are estimated by comparing minimum travel time for each OD group minus passenger walking times. The train capacity is estimated based on the number of people on the train when the passengers' travel time differs even though passengers enter the station at the same time.

The optimization model is formulated using the passenger waiting time estimated from the data. In the model, train departure times are decision variable and the objective function is
to minimize passenger waiting time and oversaturation time. When the passenger volume exceeds the train capacity, the late passengers are set to wait for the next train.

To evaluate the model, we reconstruct the hypothetical passengers using only the origin, destination, and tab-in time of the passenger in the AFC data. Genetic algorithms are used to solve the model. The genetic algorithm changes the train departure time for each iteration to minimize passengers' waiting and oversaturation times.

### 3.2. Dataset

Our data set is the subway smart card transaction data from AFC from the city of Daegu, Korea. The Daegu City subway has 85 stations ( 82 if stations connected by transfers are counted as single stations) serving 3 subway lines.

Figure 3. Daegu subway network.
Passenger transaction data from May 02, 2018, to May 29, 2018, was used as the dataset in this study. For the sake of simplicity, we select the 10 stations as the station for optimization and those stations are displayed in Figure 3.

The abbreviation of each station and their average daily boarding and alighting passenger volume for the period are listed in Table 1. We have minimized the waiting time for a single station and for all stations. We will call this the local case and the global case. To address the local case, the DR station was chosen. This is because the DR station is located in a popular residential area and a large park.

Table 1. Average daily ridership (May 2018).

### 3.3. Scenario Analysis

In the subway system, the passenger demand usually varies between the peak-hours and off-peak hours. Generally, the frequency of service trains is increased during peak hours and decreased during off-peak hours. Taking the Daegu subway system as an example, the headway time for peak hours is 6 minutes and that for off-peak hours is 10 minutes. Therefore, we assume that 10 and 6 trains per hour are available for peak and off-peak hours, respectively.

Figure 4. Daily ridership at DR station on Wednesday, May 2018.

### 3.3.1. Peak hours Scenario

Many commuters take the subway to and from their company and home in the morning and the evening (called peak hours). At the typical peak hours, the passenger demand is steadily higher than ever. And the time interval between trains is shorter than at other times. In the experiment, we used the evening peak on 23 May in the experiment shown in Figure 4.

### 3.3.2. Congested Off-peak Hours Scenario

When festivals or concerts are held in certain places, passenger volume at nearby subway stations increases more than other times. Often these events take place during off-peak hours. On May 19, shown in Figure 5(a), a big lantern festival was held in a park near the DR station. The organizer estimated that 20,000 people participated in the festival. The original data for the oversaturation case is shown in Figure 5(a), to evaluate the optimization effect according
to the pattern of passenger arrival rate, we synthesized two more passenger data from the original data, which is shown in Figures 5(b) and (c). Figure 5(b) shows the data with double peaks and Figure 5(c) shows the data with a box-shaped peak. With those synthesized data, we compare the effect of the waiting time optimization according to the passenger arrival pattern.

(a)

(b)

(c)

Figure 5. Daily ridership at DR station on Saturday, May 2018 (a) Single peak (SP) scenario (b) Double peak scenario (c) Box-shaped peak scenario.

## IV. PROBLEM FORMULATION

### 4.1. Assumptions

To reduce the complexity of computation, we used passenger data that used only 10 stations in Figure 3. Also, we make several assumptions to make the problem more tractable. Assumptions are explained as follows:

Assumption 1. Each passenger satisfies the first-in-first-out (FIFO) property. Passengers who first enter the subway station earlier can board the train earlier.

Assumption 2. The number of alighting people has no effect on passenger's walking up/down time.

Assumption 3. The walking time of a normal passenger from the turnstile to the platform is the same as that from the platform to the turnstile.

Assumption 4. The passenger cannot board on the train if the number of passengers in the train exceeds the capacity of the train.

Assumption 5. Passengers are distributed uniformly in each carriage. There is no case that one carriage is oversaturated and there is space for passengers in the other carriages.

The parameters and notations used in this research are summarized in Table 2.

Table 2. Parameters.

| Notation | Description |
| :---: | :---: |
| $t_{\text {in }}$ | Time a passenger enters a station via turnstile |
| $t_{\text {out }}$ | Time a passenger exits a station via turnstile |
| $t_{o n}$ | Time a passenger enters a train |
| $t_{\text {off }}$ | Time a passenger exits a train |
| $T_{i j}\left(t_{i n}\right)$ | Total travel time from station $i$ to station j when a passenger taps in at station $i$ at time $t_{i n}(\mathrm{sec})$ |
| $T_{i}^{K}$ | Walking time from the platform of station $i$ to the turnstile |
| $T_{i}^{D}$ | Dwell time of station $i$ |
| $T_{i}^{W}\left(t_{i n}\right)$ | Waiting time for a train on the platform when a passenger taps in at station $i$ at time $t_{i n}$ |
| $T_{i j}^{R}$ | Riding time in the train when traveling from station $i$ to station $j$ (sec) |
| $N_{t r}$ | Number of available trains on the time horizon |
| $\tau=\left\{t d_{1}, t d_{2}, \cdots, t d_{N_{t r}}\right\}$ | Set of train departure times (sec) |
| $a_{i k}$ | Time train $k$ arrive at station $i$ |
| $V_{k}(t, t d)$ | Passenger volume on train $k$ at time $t$ |
| $V_{i}(t)$ | Passenger volume on platform i at time $t$ |
| $C_{\text {max }}$ | Maximum capacity of a train |
| $N_{s k}$ | Number of skipped trains |

### 4.2. Train Capacity

We perform the experiments only in a single subway line. To represent a more realistic situation, train capacity needs to be scaled down. We filter out the passengers who transfer to other lines and it has the same effect as the train capacity becomes larger. Before downsizing the system, it is important to determine how much to reduce train capacity. It is important to determine how much to reduce train capacity. To determine the train capacity, we used the following procedure. First, the train schedule is maintained. Then we adjust the train capacity such that the expected passenger waiting time in the scaled-down system is equal to the average waiting time in the original system. (The procedure for calculating passenger waiting time is described in detail in the next subsection.) Following this process, we resized the train capacity from 1902 to 397 passengers.

### 4.3. Passenger Volume Estimation

To minimize passenger waiting time, it is necessary to consider the passenger volume and train capacity. This is because the oversaturated train causes long waiting time for passengers and potential accident risks on the platform. In this paper, the oversaturation time is defined
as time length that at least one passenger at the station is unable to ride the coming train due to many people on the train. In the following, the detailed passenger volume estimation will be proposed.

### 4.3.1. Passenger Volume on the Train

In this step, we estimate the passenger volume on the train by utilizing the AFC data. We use the DBSCAN and the travel time decomposition for calculating the passenger volume. The DBSCAN is chosen for clustering passengers on each train because it does not need the number of clusters in the data in advance and it is robust to outliers. The travel time decomposition is employed since it is conceptually simple and requires low computation.

The procedure to estimate the passenger volume is as follows. First, we extract each component of the travel time from the AFC data, such as walking, waiting and riding as shown in Figure 6. When a passenger travels from the station $i$ to the station $j$, we decompose the travel time of the passenger as

$$
\begin{equation*}
T_{i j}\left(t_{\text {in }}\right)=t_{\text {out }}-t_{\text {in }}=T_{i}^{K}+T_{i}^{W}\left(t_{\text {in }}\right)+T_{i j}^{R}+T_{j}^{K} . \tag{1}
\end{equation*}
$$

Figure 6. Travel time decomposition.

Figure 7. Clustered passengers who traveled from station $\boldsymbol{i}$ to station $\boldsymbol{j}$.

In Figure 7, data points that are represented with the same color indicate the passengers
riding the same train. We assume that the point with the smallest travel time, denoted by $T_{i j}^{*}$,
in a cluster has zero waiting time. Then, the waiting time of each passenger in the same cluster
is calculated by subtracting the smallest travel time from each travel time as follows

$$
\begin{equation*}
T_{i}^{W}\left(t_{i n}\right)=T_{i j}\left(t_{i n}\right)-T_{i j}^{*} . \tag{2}
\end{equation*}
$$

The same procedure is repeated for other clusters. The trend lines for the clusters is mathematically expressed by the equation

$$
\begin{equation*}
y=-x+T_{i j}^{*}+a_{i k}\left(a_{i(k-1)} \leq x \leq a_{i k}\right) \tag{3}
\end{equation*}
$$

The walking time of passenger at station $j$ is obtained by

$$
\begin{equation*}
T_{j}^{K}=\frac{T_{i j}^{*}+T_{j k}^{*}-T_{i k}^{*}+T_{i}^{D}}{2}, \tag{4}
\end{equation*}
$$

when the train travels in the order of the station $i, j$ and $k$. We assume that the dwell time $T_{i}^{D}$ is 30 seconds at peak hours scenario and one minute at off-peak hours scenario.

The riding time is calculated by subtracting walking time and riding time from the travel time as

$$
\begin{equation*}
T_{i j}^{R}=T_{i j}\left(t_{i n}\right)-T_{i}^{K}-T_{i}^{W}\left(t_{i n}\right)-T_{j}^{K} . \tag{5}
\end{equation*}
$$

As a result, components of the travel time are obtained for a passenger who is traveling from station $i$ to $j$ who enters station $i$ at $t_{i n}$.

To calculate the number of passengers on each train by using each component of travel time, Heaviside function $\mathrm{H}(\mathrm{t})$, defined by 0 when $\mathrm{t}<0$, and by 1 otherwise, is used. Thereafter, the passenger volume on the train is calculated by summing each passenger riding time [9] as

Figure 8 shows the passenger volume in each train obtained from the AFC data.

$$
\begin{align*}
V_{k}(t, h)= & \sum_{\text {train }=k} H\left(t-t_{o n}\right)-H\left(t-t_{o f f}\right) \\
= & \sum_{\text {train }=k} H\left(t-t_{o n}\right)-H\left(t-\left(t_{o n}+T_{i j}^{R}\right)\right)  \tag{6}\\
= & H\left(t-\left(t_{\text {in }}+T_{i}^{K}+T_{i}^{W}\left(t_{\text {in }}\right)\right)\right. \\
& \sum_{\text {train }=k}-H\left(t-\left(t_{\text {in }}+T_{i}^{K}+T_{i}^{W}\left(t_{i n}\right)+T_{i j}^{R}\right)\right) .
\end{align*}
$$

Figure 8. Passenger volume in each train.

### 4.3.2. Passenger Volume on the Platform

Passenger volume on the platform is used to determine the number of passengers waiting for a train at the station. It is calculated in the same way from Equation (1) to (5). In this case, instead of the riding time in the Equation (6), the walking time and the waiting time of each passenger at the station are summing.

### 4.4. Timetable Optimization Model

In order to minimize the passenger waiting time and oversaturation time, we develop a model to optimize the train. In this study, we assume that the train speeds are the same as usual. Therefore, the most important decision variables are the departure time of each train at the start terminal. We aim to minimize the average waiting time and the maximum waiting time by controlling the train departure time and applying the train skip plan. The optimization is performed for both local and global cases. The local case minimizes the passenger waiting time of a specific station, while the global case minimizes the passenger waiting time of all stations in the system. In addition, when the oversaturation occurs, we minimize the passenger waiting time and oversaturation time by controlling the train departure time and the number of skipped trains.

### 4.4.1. Train Departure Time Control

### 4.4.1.1. Passenger Waiting Time Minimization Problem

The goal is to minimize the passenger waiting time by controlling the set of train departure times. We set the headway constraint to prevent train car collision and long passenger waiting time. The headway is defined as the time interval between trains as follows.

$$
\begin{equation*}
h=t d_{i}-t d_{i-1} \tag{7}
\end{equation*}
$$

where $i-1$ is the number given to the preceding train and $i$ is the number given to the train immediately following the train $i-1$. We formulated several optimization problems according to the values that should be minimized. When the goal is to minimize the average of the waiting time for passengers at a particular station, the optimization problem for average passenger waiting time is defined as Equation (8) In this problem, the objective function is to minimize the average of the waiting times for passengers at a station $i$, which is called as LAWT (Local Average Waiting Time).

\[

\]

When the goal is to minimize passenger waiting time at all stations in the subway system, then the optimization problem for average passenger wait time is defined as Equation (9). In this problem, the objective function is to minimize the average waiting time of all passengers in the subway system which is called GAWT (Global Average Waiting Time).

\[

\]

When the goal is to minimize the maximum passenger waiting time for a particular station, the optimization problem for maximum passenger wait time is defined as Equation (10). The objective function is to minimize the maximum value of waiting times for passengers whose station $i$ is the origin, which is called LMWT (Global Maximum Waiting Time).

\[

\]

To minimize the maximum passenger waiting time in the subway system, the optimization problem for maximum passenger wait time is defined as Equation (11). The objective
function is to minimize the maximum waiting times for passengers at all stations in the subway system. This is called GMWT (Global Maximum Waiting Time).

\[

\]

The decision variable in this optimization problem is the set of train departure times. The relationship between the passenger waiting time and the train departure time is expressed as Equation (12). The passenger waiting time for passengers who entered at $t_{i n}$ in station $i$ is obtained by subtracting the sum of the time that the passenger entered the station and passenger walking time from the sum of the train departure time at first terminal and time length that the train ran from the first terminal to station $i$.

$$
\begin{align*}
& T_{i}^{W}\left(t_{i n}\right)=t d_{k}+T_{a i}^{R}-\left(t_{i n}+T_{i}^{K}\right) \\
& \text { for } t d_{k-1}+T_{a i}^{R}<t_{i n}+T_{i}^{K}  \tag{12}\\
& \leq t d_{k}+T_{a i}^{R} ; a>1 ; i>a .
\end{align*}
$$

### 4.4.1.2. Oversaturation Time Minimization Problem

When oversaturation occurs, we control the train departure time to minimize the oversaturation. The oversaturated time (OST) is the time length that at least one passenger at the station is unable to ride the incoming train because the train is in full capacity. OST is defined as :

$$
\begin{align*}
& \mathrm{OST}=t d_{i}-t d_{i-j} \\
& \quad \text { for } i=2,3, \ldots, N_{t r} ; \mathrm{i}-\mathrm{j}>1 ; C_{\max }<V_{k}(t) \text { for } \exists k . \tag{13}
\end{align*}
$$

Oversaturation time minimization is only performed when the passenger volume in the train exceeds the train maximum capacity. As with waiting time optimization, there is a headway constraint to prevent car crashes and long waits for passengers. The optimization problem to minimize the oversaturation time is expressed as follows.

\[

\]

### 4.4.2. Train Skip Plan Control

When oversaturation occurs at a particular station, the oversaturation time and passenger
waiting time can be reduced by letting the trains directly go to the congested station by skipping previous stations. In the optimization problem to minimize passenger waiting time and oversaturation time, the decision variable is the number of trains that skip previous stations. Other parts of the equation, such as decision variables and objective functions and constraints, are similar to Equations (8)-(11) with different constraints. The optimization for LAWT is expressed in Equation (15) and the optimization for GAWT, LMW, GMWT, and OST are expressed in Equations (16)-(19) respectively.

### 4.5.1. Genetic Algorithm

To solve the formulated problem, we apply the genetic algorithm (GA) [13]. GA is a heuristic search algorithm to optimize problems based on natural evolution. GA is widely applied in the train scheduling researches [14][15]. It is because GA has the advantage of requiring less computational resources and being able to perform very large calculations in a relatively short time compared to mathematical formulation approaches such as neural networks.

## Table 3. Pseudocode for Genetic algorithm.

```
Function Genetic Algorithm (POP_SIZE, START, END, GENERATION, AVAILABLE_TRAIN)
```

As Train Scheduling

```
Begin
    P = Generate_Initial_Population(POP_SIZE, START, END, AVAILABLE_TRAIN)
    for i = 1 to GENERATION step 1 do
        S = Selection(P)
        C = Crossover(S)
        M = Mutation(S)
        P=S +C+M
        if i == (GENERATION-1):
            BEST_SOLUTION = Evaluate(P)
    return BEST_SOLUTION
end
```

This algorithm is applied to our research as follows. First, an initial population called P is generated when we enter the inputs such as the time window of the scheduling and the number of available trains. Each initial population is modified by applying selection, crossover, and mutation procedures. These procedures are repeated for the given generation number. If there are n solutions in the parent population, the offspring population is composed by sum of three small populations: 1) $x$ selected individuals whose the fitness value, that is evaluated by the fitness function, is greater than other individuals 2) $y$ individuals with crossover opera-
tion applied to the selected individuals and 3) $n-x-y$ individuals with mutation operation applied to selected individual. In this experiment, two of 10 individuals were selected, four individuals crossed over, and four were mutated. During the last iteration, each individual in the population is evaluated and the solution with low waiting time (or lowest oversaturation time) is returned with the best solution.

## V. EVALUATION

In order to evaluate the performance of our system, we optimize local average waiting time (LAWT), global average waiting time (GAWT), local maximum waiting time (LMWT) and global maximum waiting time (GMWT) by controlling the train departure time from the start terminal station. We evaluate the improvement for two scenarios: peak hours and congested off-peak hours. To evaluate the effect of the train skip plan, we figure out the improvement of the waiting time and oversaturation time (OST) by skipping the first 0 to 3 trains out of 6 trains operated over an hour especially in the oversaturated train scenario. We also optimize OST and then evaluate how much OST, LAWT, GAWT, LMWT, and GMWT have been decreased. All results improvement is expressed as (old(seconds) - new(seconds)) / old (seconds) * $100 \%$.

We estimated from the AFC data that there were 10 trains per hour during peak hours and 6 trains per hour during off-peak hours. The experiment was carried out with the same number of trains. To prevent car crashes and long waiting times, the minimum headway was constrained to 3 minute and the maximum headway was constrained to 15 minutes. To solve the problem, each genetic algorithm takes 100 iterations to reach the optimal solution. Each optimization was performed 5 times and more detailed experimental results are in Appendix A.

### 5.1. Peak hours scenario

In peak hours scenarios, GAWT and LAWT are decreased by 19\% and GMWT by $35 \%$ and it is most desirable to use GAWT as an objective function to reduce both AWT and MWT.

Note that LAWT is significantly reduced when GAWT is minimized compare to the case when LAWT is used as an objective function. As shown in Figure 9(a), when LAWT is minimizing, LAWT is reduced by $13 \%$. However, in Figure 9(b) when GAWT is minimizing, LAWT is reduced by $19 \%$. This is due to the fact that the optimization result is more likely to get stuck in a local minimum because the amount of the data used in the calculation when LAWT is used as an objective function is less than that of GAWT.

In Figure 9(a) and (b), MWT is decreased by up to $35 \%$ when minimizing AWT. However, when minimizing MWT, AWT is decreased by up to $10 \%$ in Figure 9(c), and sometimes AWT is increased as shown in Figure $9(\mathrm{~d})$. This is because the objective function for AWT is to utilize the entire passenger data, whereas the objective function for MWT is to use only one passenger data of maximum waiting time.

(a)

(c)

Figure 9. Improvement comparison of waiting time by types of optimization at peak

## hours scenario. (a) Local average waiting time optimization (b) Global average waiting time optimization (c) Local maximum waiting time optimization (d) Global maximum waiting time optimization

### 5.2. Congested off-peak hours scenario

In the oversaturation scenario, we minimized AWT or MWT depending on the number of trains skipped out of six trains, along with the departure time of each train. Figures 10 to 12 indicate the outcome evaluations on the train scheduling optimization of saturated scenario.

The number of passengers in Figures 10 to 12 is the same, but the passenger arrival pattern differs by a single peak, double peak, and box-shaped peak, respectively. Each figure shows that even if the number of boarding passengers is the same, the effect of optimization can be different according to the passenger arrival pattern.

### 5.2.1. Single peak oversaturation

In the single peak oversaturation case, as shown in Figure 10(b), AWT is decreased by
up to $36 \%$ and MWT by up to $56 \%$ when using GAWT as an objective function. In Figure 10(a), When minimizing LAWT, AWT is reduced up to $36 \%$, which does not show a significant difference when compared with minimizing GAWT.

It is desirable to use AWT than MWT as the objective function to decrease both AWT and MWT with low computation at the single peak case. As shown in Figures 10(a) to (b), MWT is reduced when AWT was minimized but Figures 10(c) and (d) represent that AWT was increased when MWT was minimized. This is presumably because the headway is reduced on a single peak with the highest passenger arrival rate, and the waiting time for people arriving at the train station is longer when it is relatively less crowded. In addition, MWT is significantly reduced when AWT is the objective function than when MWT is the objective function. In Figure 10(d), LMWT and GMWT are decreased by $37 \%$ and $42 \%$, respectively, while when the objective function is GAWT they are decreased by $51 \%$ and $56 \%$, respectively as shown in Figure 10(b). This is because minimizing MWT requires more iterations in the GA than minimizing AWT.

When comparing GAWT and LAWT as the objective function of the optimization, GAWT yielded slightly better performance. As shown in Figure 10(b), LAWT and GAWT are decreased by $36 \%$ and $33 \%$, respectively, when GAWT was objective function, and when LAWT was objective function LAWT and GAWT is decreased by $36 \%$ and $28 \%$ respectively which is shown in Figure 10(a). In addition, OST is also reduced by $12 \%$ when GAWT is the objective function while with LAWT it is reduced by $6 \%$.

Minimizing oversaturation time has very little to do with minimizing the waiting time. As shown in Figure 10(e), OST is reduced by up to $37 \%$ when OST is the objective function. However, AWT is increased by up to $80 \%$, and MWT is decreased up to $13 \%$.

(a) Local average waiting time optimization (b) Global average waiting time optimization (c) Local maximum waiting time optimization (d) Global maximum waiting time optimization (e) Oversaturation time optimization.

### 5.2.2. Double peak oversaturation

In the double peak oversaturation scenario, as shown in Figure 11 (a), LAWT and GAWT are decreased by up to $39 \%$ and $29 \%$ respectively and GMWT is decreased by $22 \%$ in Figure 11(d).

Note that MWT is increased when AWT is minimized shown in Figures 11(a) and (b). This is because that MWT increases by the time distance between two peaks. Therefore, minimizing AWT does not help reduce MWT when there is a large time interval between peaks.

In Figures 11(c) and (d), OST is decreased by $55 \%$ when using MWT as the objective function, especially GMWT as the objective function. Using OST as the objective function in

Figure $11(\mathrm{e})$, OST is decreased by $53 \%$, but AWT and MWT are increased. Therefore, in order to minimize AWT, MWT and OST, it is most desirable to use each of them as an objective function.

Figures 11(a) to (d) indicate that the number of skipped trains that minimizes AWT and MWT is different. To reduce AWT, we do not need to skip the train, but it is desirable to skip the train to reduce MWT further. Figure 11(e) presents minimizing oversaturation time does not help reduce the waiting time.

(a)

(b)

(c)

(a) Local average waiting time optimization (b) Global average waiting time optimization (c) Local maximum waiting time optimization (d) Global maximum waiting time optimization (e) Oversaturation time optimization.

### 5.2.3. Box-shaped peak oversaturation

In the box-shaped peak oversaturation scenario, LAWT and GAWT are decreased by up to $56 \%$ and $47 \%$ respectively in Figures 12(a) and (b). As shown in Figure 12(c) GMWT is decreased by up to $42 \%$ when one train is skipped.

As shown in Figures 12(a) to (d), whatever the objective function is, all variables are decreased together. This is because train arrival intervals are optimized on a regular basis as passenger arrival rates are nearly constant by time.

Figure 12(e) indicates that minimizing OST reduces MWT by up to $38 \%$ and increases AWT by up to $26 \%$.

### 5.3. Discussion

We found that the effect of optimization on the objective function varies according to the passenger arrival pattern. In particular, the effectiveness of optimization in a congested situation depends on the uniformity of the passenger arrival pattern of the congested local station. In the oversaturation of the box-shaped peak, whichever is chosen as the objective function, AWT and MWT are minimized together because the arrival rate of passengers is uniform which is shown in Figure 12. On the other hand, AWT and MWT do not decrease together when the passenger arrival pattern is not uniformly distributed such as single-peaked and dou-ble-peaked oversaturation. In the case of single peaked oversaturation, AWT and MWT decreased only when AWT was used as the objective function. In double-peaked oversaturation, we observe that the closer the distance between the two peaks, the greater the decrease in AWT and MWT. Therefore, the operator may consider various decisions depending on the passenger arrival pattern and their purpose. If the operator would like to reduce AWT or MWT, they might set AWT or MWT to their objective function and minimize it. The optimization result will be a new train departure timetable that serves that purpose. However, it should be noted that if the passenger arrival pattern is not uniform, a trade-off may occur between MWT and AWT when MWT is minimized.

When it comes to the relationship between WT and OST, OST and MWT had little correlation except for the uniform passenger arrival pattern. OST decreases when MWT is reduced in double peak and box-shaped peak oversaturation. However, when the OST is reduced, the MWT is reduced only if the passenger arrival pattern is uniform.

Applying the train skip plan reduces WT more, especially MWT. However, the train skip plan has the disadvantage of increasing the passenger waiting time of skipped stations. Therefore, using the train skip plan can be considered when there is an urgent need to deal with the high congestion of certain stations.

## VI. CONCLUSION AND FUTURE WORK

Highly congested trains are often a major factor in poor passenger service in the subway system. To solve this problem, we optimized the train timetable to minimize passenger waiting time for each scenario of peak hours and congested off-peak hours by controlling the train departure time and the number of skipped trains. Our system reduces LAWT by up to $56 \%$ at oversaturation. The experiment results demonstrate that adjusting the train departure time and the train skip plan reduce the waiting time more in the highly congested situation. When we skipped the trains in an oversaturation scenario, AWT and MWT are further reduced up to $15 \%$ and $19 \%$ respectively in the box-shaped oversaturation scenario.

Moreover, we compared how the effect of optimization varies with each passenger arrival pattern when oversaturation occurs. As a result, we found that AWT and MWT to be minimized together when the arrival rate of passengers is uniform. The proposed approach will not only help train scheduling in congestion situations but also help to estimate the optimization effect according to the passenger arrival pattern.

Our future work will consider extending the transfer time when the single line is extended to multiple lines and the real-time operation of the system. Moreover, since we used previous data to optimize train scheduling, it will also be useful to predict the oversaturation by utilizing
the real-time data. In addition, we assume that passenger walking time is not affected by passenger volume, however that assumption is not realistic. Therefore, it would be good to make a more detailed model of the passenger walking time to improve the accuracy of the model by considering the effect on the walking time of the passengers when there are a lot of passengers on the platform.

## 요 약 문

## 도시 지하철역에서의 예기치 않은 혼잡에 대한 처리 방안

도시 지하철은 도로교통 상황의 영향을 크게 받지 않으며 대용량의 교통 수요를 처리할 수 있어 많은 승객들에게 이용된다. 혼잡한 지하철은 승객들에게 불편을 야기하며, 승객들의 승강장에서의 대기시간을 증가시킨다. 본 논문은 열차 출발 시간과 역들을 건너 뛴 열차 수를 조절하여 승객 대기 시간을 최소화하는 것을 목표로 한 열차 시간표 최적화 방안을 제시한다. 승객 도착 통계 모델에 의존하는 기존의 접근 방식과 달리, 이 연구는 대구의 지하철에서 수집된 교통카드 데이터들을 기반으로 하는 최적화 모델을 만든다. 모델은 각 승객의 여행 시간을 차량 대기 시간, 차량 탑승 시간 및 보행 시간으로 구분하고, 탑승한 기차에 따라 승객들을 군집화 시킨 후 각 차량마다 승객 수를 추정하는 것으로 구성된다. 이를 바탕으로 주어진 열차 스케줄에 대해 모든 승객 각각의 대기 시간들을 계산할 수 있다. 최적화 문제는 이용 가능한 열차 수, 열차가 수용 가능한 최대 승객 수, 폐색구간과 같은 현실적인 제약 조건 하에서 구성된다. 최적의 시간표를 찾기 위한 방법으로 유전자 알고리즘이 사용되었다. 그 결과 승객 평균 대기 시간은 최대 $56 \%$ 까지 단축되었으며, 열차 출발시간 뿐만 아니라 일부 역을 건너뛰는 열차의 수까지 최적화하면 매우 혼잡한 상황에서 더 나은 결과를 얻을 수 있었다. 혼잡한 상황에서 기차가 일부 역을 건너뛰었을 때, 그렇지 않을 때보다 승객 최대 대기 시간은 $19 \%$, 승객 평균 대기 시간은 $15 \%$ 정도 더욱 단축되었다. 또한 혼잡한 상황에서 승객 도착 패턴에 따라 최적화의 효율이 달라진다는 것을 확인하였다. 본 방안은 승객 평균 대기시간을 감소시킴으로써 지하철 서비스를 향상시킬 것이다.

핵심어: 열차 시간표 최적화, 승객 대기시간, 유전자 알고리즘
